The details of the topographic relations between the spinal cord and the vertebrae are important to understand the physiology of the central nervous system. These relations have been studied in cattle (Habel, 1951), sheep (Goller, 1957), goat (Sharma et al., 1973) and horse. However, the information in camel is lacking in the literature barring a few fragmentary reports (Hifny et al., 1985). Therefore, the present investigation was carried out to record the topographic relations between the spinal cord segments and the corresponding vertebrae in camel.

**MATERIALS AND METHODS**

During present study six apparently healthy adult camels were embalmed with 10% formalin as per standard technique. The spinal cord was exposed both ways, dorsally by laminectomy and laterally by paramedian section using an electric saw. A close search was made with naked eye and a hand lens to examine the surface and extent of the each spinal cord segment and the corresponding vertebra in the vertebral canal to establish their topographic relations.

**RESULTS AND DISCUSSION**

Camel possessed the longest spinal cord among the domesticated animals. It extended from the level of the foramen magnum to the end of the second sacral vertebra as reported earlier (Hifny et al., 1985), however, sometimes it terminated at the cranial one third of the second sacral vertebra or to sacrum. (Smuts and Bezuidenhout, 1987). Sharma and Rao (1971) reported that the termination of spinal cord took place at the middle of the sacrum in Indian buffalo while in Egyptian buffalo at the cranial limit of the third sacral vertebra (Abu-Zaid, 1982). The termination of the spinal cord in ox occurred at the level of first sacral vertebra (Habel, 1951) or at middle of the sacrum (McLeod, 1958). However, in goat the spinal cord terminated at the caudal end of the third sacral vertebra (Sharma et al., 1973). The average length of the spinal cord in camel was 214.02 cm. It measured 138.67 cm in Indian buffalo (Sharma and Rao, 1971), 188.65 cm in Egyptian buffalo (Abu-Zaid, 1982) and 54.5 to 56.2 cm in goat (Sharma et al., 1973).

The cervical enlargement in camel extended from C₆ to T₄ as reported earlier (Hifny et al., 1985) and in Indian buffalo (Abu-Zaid, 1982). In Egyptian buffalo (Abu-Zaid, 1982), it extended from C₅ to T₁ where as in sheep from C₆ to T₁ (Goller, 1957). The lumbar enlargement extended from L₅ to S₁ in camel, it extended from L₁ to S₁ in Indian buffalo (Sharma and Rao, 1971), from L₄ to S₁ in sheep and goat (Goller, 1957, Sharma et al., 1973) and from L₄ to S₂ in Egyptian buffalo (Abu-Zaid, 1982).

The whole cervical part of the spinal cord
occupied its corresponding cervical portion of the vertebral column in camel. The segmental length in the cervical region rapidly increased from $C_1$ (6.0 cm) to $C_5$ (17.0 cm) followed by a sharp decrease in length till $T_1$ (5.0 cm). The segment length in the thoracic region showed a gradual increase from $T_1$ (5.0 cm) to $T_5$ (7.5 cm), followed by an approximately constant length up to $T_{12}$ with an average of 8.0 cm. The cranial displacement of the thoracic spinal segments from 2nd to 8th in camel were similar to the results as reported in Indian buffalo (Sharma and Rao, 1971).

The lumbar region showed a remarkable decrease in the segment length from $L_1$ (7.0 cm) to $L_7$ (2.0 cm) followed by a gradual decrease from the $L_7$ to the termination of the spinal cord at coccygeal vertebra ($C_5$, 0.5 cm). The first five lumbar spinal cord segments showed a caudal displacement. In camel the cranial displacement began at the 7th lumbar spinal segment was also reported in Egyptian buffalo at 6th segment (Abu-Zaid, 1982), 4th in cattle (Dellmann and McLure, 1975) and 2nd lumbar segment in Indian buffalo (Sharma and Rao, 1971).

The average transverse diameter of the spinal cord at its beginning was 1.32 cm, it gradually increased caudally and was highest at the level of $C_8$ (1.70 cm) and $T_1$ (1.60 cm) where it formed the cervical enlargement (intumescentia cervicalis) and then again there was a gradual decrease in the diameter and smallest of which was recorded at the level of $T_{12}$ (0.98 cm). From the level of $T_{10}$ the diameter again started increasing gradually and became large at $L_7$ (1.40 cm) and $S_1$ (1.38 cm) which formed the lumbosacral enlargement (intumescentia lumbalis). These two enlargements represented the origin of the brachial and lumbosacral plexuses, respectively.

The number of nerve rootlets was directly proportional to the transverse diameter of the spinal cord. The average number of nerve rootlets was 25 at the level of $C_1$, 70 at the $C_8$, and 68 (cervical enlargement) at $T_1$ and it was again recorded 25 at $T_3$ and 26 at $T_{12}$ level and then again started increasing gradually caudally to 54 at $L_7$ and 52 at $S_1$ (lumbar enlargement). The conus medullaris segment of the spinal cord showed the least number of the rootlets and the minimum number was at $C_0$, level.

**Relation between spinal cord segments and body of vertebrae**

The first segment of the cervical spinal cord laid entirely in the atlas, while the second segment covered the cranial 2/3rd of the axis. The third to seventh cervical segments showed a cranial displacement by a distance ranging between 5.3 – 9.0 cm. The last cervical segment occupied the cranial 2/3rd part of the last cervical vertebra (Fig 1). The maximum cranial displacement was observed at the third, while the minimum at the seventh cervical vertebra segment.

The first segment of the thoracic spinal cord occupied the caudal 1/3rd of the last cervical vertebra and cranial half of the first thoracic vertebra. The second, third and fourth thoracic segments were completely displaced cranially from their corresponding thoracic vertebra to occupy the body of the preceding one. The 5th to 9th thoracic segments were located at the level of their corresponding vertebra and 9th thoracic segment terminated at the level of caudal border of the body of the corresponding vertebra. Last three thoracic segments showed a caudal displacement ranging between 2.5 – 3.0 cm.

The first five lumbar spinal segments showed a caudal displacement ranging between 2.0 – 3.0 cm. The last two lumbar segments were lodged with in the 6th lumbar vertebra. So the 6th lumbar vertebra occupied the caudal part of 5th, 6th and 7th segments. The sacral spinal segments...
were comparatively smaller and all the five segments were lodged with in the last lumbar vertebra. Similar finding has been reported earlier (Hifny et al., 1985). The coccygeal spinal segments were also comparatively smaller and tapered forming the conus medullaris. All the five segments were lodged in to the first, second and cranial half of the 3rd sacral vertebra where the spinal cord term inated.

**Relation between spinal cord segments and spinous processes**

The relationship was calculated by drawing a vertical line between the caudal margin of the summits of spinous processes and corresponding spinal cord segment. The dorsal tubercle of atlas vertebra was related vertically to cranial 1/4th of the second cervical segment, while the spinous process of second cervical vertebra (axis) laid opposite to the cranial 1/3rd of the third cervical segment. The spinous process of last cervical vertebra was related vertically to caudal margin of the 8th cervical segment (Fig 1).

The spinous process of first thoracic vertebra laid at the level of caudal 1/3rd part of third thoracic segment, while those of 2nd, 3rd and 4th thoracic vertebrae were related to caudal 1/5th of the 4th, 5th and 6th thoracic segments, respectively. The spinous processes of 9th and 10th thoracic vertebrae were located at the level of 10th and 11th thoracic segments, respectively, while those of the last two thoracic vertebrae were related to their corresponding segments. Almost similar findings had been reported in this species (Hifny et al., 1985).

The caudal margin of spinous process of first lumbar vertebra was related vertically to the caudal 1/4th of first lumbar segment. The spinous process of 5th and 6th lumbar vertebrae was placed opposite to their corresponding segments, while that of last lumbar vertebra was present opposite to the end of the sacral segment. Hifny et al. (1985) stated that the spinous process of first lumbar vertebra laid vertical to the caudal most 1/3rd of the last thoracic segment, while that of the last lumbar vertebra opposite to the middle of the 4th lumbar segment.

**Relation between spinal cord segments and transverse processes**

The relationship was calculated on the basis of drawing a transverse line from the caudo-lateral angle of the transverse processes to the spinal cord segment (Fig 2). The wing of atlas vertebra laid at the level of cranial 1/4th of second cervical segment, while the transverse processes of second and third cervical vertebrae laid at the cranial 1/3rd of the third and fourth cervical segments. The transverse processes of 4th, 5th and 6th cervical vertebrae were present at the level of middle of the 5th, 6th and 7th cervical segments, respectively. However, the transverse process of last cervical vertebra laid opposite to the caudal margin of 8th cervical segment. The transverse processes of first six thoracic vertebrae lay opposite to their next corresponding spinal cord segments, while the last six transverse processes were placed opposite to their corresponding segments. The transverse processes of lumbar vertebrae were generally related to their corresponding lumbar spinal cord segments. The cranial border of the wing of sacrum laid opposite to the caudal end of 3rd sacral spinal segment.
